Title of the Master Thesis : Point Based Correspondenceless Pose Estimation  
Name/Last Name of the Student : Ferhat CANBAY  
Date of Thesis Defense : 26.08.2009

The thesis has been approved by the Graduate School of Natural and Applied Sciences.

Prof. Dr. A. Bülent ÖZGÜLER  
Director

This is to certify that we have read this thesis and that we find it fully adequate in scope, quality and content, as a thesis for the degree of Master of Science.

Examining Committee Members:

Asst. Prof. Dr. Sezer GÖREN UĞURDAĞ (Supervisor) :

Asst. Prof. Dr. H. Fatih UĞURDAĞ :

Prof. Dr. Nizamettin AYDIN :

## **ACKNOWLEDGEMENT**

I would like to thank Dr. Sezer GÖREN UĞURDAĞ and Dr. H. Fatih UĞURDAĞ, for their guidance, encouragement, support, valuable comments and constructive suggestions throughout my study. Also I thank to my family for their understanding during the study.

## ÖZET

CORRESPONDENCELESS POINT BASED POSE ESTIMATION

Günümüzde, hayatımızı kolaylaştıran teknolojilerden biri hiç kuşkusuz görüntüleme sistemleridir. Görüntüleme sistemleri yalnızca görüntüleme işi yapmayıp aynı zamanda bu görüntüyü işleyerek anlamlı veriler elde etme yeteneğine sahip sistemlerdir. Herhangi bir kamera tarafından elde edilmiş bu görüntülerde bulunan bir nesnenin pozisyon ve oryantasyon'u (poz) robotlarda, filmlerde, animasyonlar gibi bir çok alanda ihtiyaç duyulan bir bilgidir. Bu tezde poz kestirimi için gerekli olan alt görevlerden öznitelik bulma süreci otomatik hale getirilmiştir. Buna ek olarak nokta temelli, karşılıklık bilgisi gerektirmeyen Gravitational Pose Estimation (GPE) ve SoftPOSIT algoritmaları birbirlerine entegre edilmiştir. Aynı zamanda nesnenin görünmeyen noktalarından kaynaklanan problem de belli ölçülerde tolere edilmiştir. Poz kestirim kısmı, gerçek ve sanal resimler kullanılmak suretiyle test edilerek başarı oranı da ayrıca kanıtlanmıştır.

Anahtar Kelimeler: Görüntüleme, Poz Kestirim, Karşılıklık Otomasyon, Öznitelik Bulma

## **ABSTRACT**

### **CORRESPONDENCELESS POINT BASED POSE ESTIMATION**

Today, one of the technologies which ease our lives is vision systems. Vision systems not only execute the task of vision but also they have the ability to process these images to extract meaningful data. The position and orientation (pose) of an object found in these images are useful information required for many fields such as robotics, films and animations. In this thesis, we automate the subtasks such as feature extraction and blob coloring that are required during the pose estimation. In addition, a correspondenceless point-based algorithm which is called Gravitational Pose Estimation (GPE) is proposed and implemented. We have also integrated GPE and SoftPOSIT into a single method called GPEsoftPOSIT, which finds the orientation within 3 degrees and the position within 10% of the object's diameter even under occlusion-the manner in which an object closer to the viewport masks (or occludes) an object further away from the viewport. The algorithm is evaluated by a series of synthetic and real images. Results show that GPE is robust, consistent, and fast (runs in less than a minute).

# 1. INTRODUCTION

In computer graphics, robotics, computer and machine vision; position and orientation (pose) estimation of a three-dimensional (3D) object in regard to a camera and etc. from two-dimensional (2D) image of the object is considered as a subtask. For instance, in production applications it is used for robot guidance. It is needed for accurately applying computer graphics objects into photographic scenes, in augmented reality. Pose estimation is medium for object recognition in computer vision. In machine vision, it is required sometimes for making accurate measurements. For many of the tasks, it is used for camera calibration before executing the primary task (recognising the pose of the camera regarding the world coordinates).

In this thesis a method that solves the pose estimation problem in real life. Also the subtasks are proposed in the thesis that required providing ease of usage for users by automating the method as much as possible. In the first part of the thesis, the concepts of pose estimation problem are introduced such as image geometry and fields of pose estimation. Part two gives an overview on previous works. The phases of feature extraction required for automation is given in part three. Pose estimation problem is presented, detailed information about Gravitational Pose Estimation (GPE) algorithm and the integration of GPE and SoftPosit algorithms are mentioned in part four. Part five comprises the test results, and part six explains the program that visually shows the trajectory of the object during the GPE runs.

## 1.1. WHAT IS POSE ESTIMATION

Pose estimation, in computer vision and in robotics, is a usual task to recognise specific objects in an image and to settle each object's position and orientation relative to some coordinate system (Shapiro and Stockman 2001). For instance, this information, afterwards, can be used to enable a robot to control an object or to avoid moving into the object. Even though, this concept is occasionally used only to characterize the orientation, the

combination of position and orientation is called as the pose of an object. Exterior orientation and translation are also used as a synonym to pose.

The image data where the pose of an object is decided from can be a single image, a stereo image pair, or an image sequence where, typically, the camera is in motion with a known speed. The objects considered can be quite general, such as and including a living being or body parts, e.g., a head or hands. Yet, the methods used for deciding the pose of an object are usually particular for a class of objects, and they cannot be expected to work well for other types of objects.

The pose can be characterized through a rotation and translation transformation that conveys the object from a reference pose to the observed pose. Hereby rotation transformation can be represented in various ways, such as a rotation matrix or a quaternion.

The particular task in deciding the pose of an object in an image (or stereo images, image sequence) is referred to as pose estimation. The pose estimation issue can be figured out in various ways depending on the image sensor configuration, and choice of methodology. Herein, two classes of methodologies can be acclaimed:

Analytic or geometric methods: Supposing that the image sensor (camera) is calibrated the mapping from 3D points in the scene and a 2D point in the image is studied. Provided that the geometry of the object is as well known, it means that the projected image of the object on the camera image is a familiar function of the object's pose. Characteristically corners or other feature points; when a set of control points on the object has been picked out, it is then likely to solve the pose transformation from a set of equations, which relate the 3D coordinates of the points with their 2D image coordinates.

Learning based methods: These methods apply the artificial learning-based system which learns the mapping from 2D image features to pose transformation. In brief, this implies that an adequately large set of images of the object, in different poses, must be put to the system during a learning phase. As the learning phase is accomplished, the system should sustain presenting a valuation of the object's pose given an image of the object.

### **1.1.1. Geometry of Picture Taking**

Geometry in computer vision is a sub-field in computer vision dealing with geometric relations conventionally by a pinhole camera amidst the 3D world and its projection into 2D image. The pinhole camera model illustrates the mathematical bond between the coordinates of a 3D point and its projection onto the image plane of a model pinhole camera (Hartley and Zisserman (2003)). Here, the camera aperture is specified as a point and no lenses are used to focus light. For instance, the model does not comprise the geometric distortions or blurring of unfocused objects which are caused by lenses and finite sized apertures, and also does not take into account that most practical cameras have the only discrete image coordinates which means that the pinhole camera model can only be used as a first order approximation of the mapping from a 3D scene to a 2D image. Its validness depends on the quality of the camera and, generally reduces from the centre of the image to the edges as lens distortion effects increase (Forsyth and Ponce 2003).

Considering of the some effects that the pinhole camera model does not take into account can be compensated for, by applying suitable coordinate transformations on the image coordinates for instance, and other effects are adequately small to be neglected on condition that a high quality camera is performed. This implies that the pinhole camera model can usually be used as a proper description regarding how a camera depicts a 3D scene in computer vision and computer graphics, as to say.

In Figure 1.1, the geometry showing the mapping of a pinhole camera is given. Figure 1.2 shows the geometry of a pinhole camera.

Figure 1.1: A diagram of a pinhole camera  
Source : <http://en.wikivisual.com>

Figure 1.2 : The geometry of a pinhole camera

- A 3D orthogonal coordinate system with its origin at O. As well, this is where the camera aperture is placed. The three axes of the coordinate system are referred to as X1, X2, X3. Axis X3 is pointing in the viewing direction of the camera which reveals as the optical axis, principal axis, or principal ray. The 3D plane that intersects with axes X1 and X2 are the front side of the camera, or principal plane.
- An image plane where the 3D world is projected through the aperture of the camera. The image plane is parallel to axes X1 and X2 which is placed at distance  $f$  from the origin O in the negative direction of the X3 axis. An applicable implementation of a pinhole camera indicates that the image plane is located such that it intersects the X3 axis at coordinate  $-f$  where  $f > 0$ .  $f$  is also referred to as the focal length of the pinhole camera.
- The intersection of the optical axis and the image plane is marked as a point R. It is mentioned that as the principal point or image center.
- Point P can be marked at coordinate  $(x_1, x_2, \text{ and } x_3)$  relative to the axis X1, X2, and X3 on anywhere in the world.
- The projection line of point P into the camera. This green line goes through point P and point Q.
- The projection of point P is symbolized as Q, onto the image plane. It is existed by the intersection of the projection line (green) and the image plane. It can be supposed that  $x_3 > 0$  which means that the intersection point is specified nicely, in any practical condition.
- There is exist a 2D coordinate system in the image plane, with an origin R and axes Y1 and Y2 , parallel to X1 and X2, in the order given. The coordinates of point Q related to this coordinate system is  $(y_1, y_2)$ .

The circular hole that controls the amount of light entering a camera, as a pinhole aperture, is supposed to be eternally small, a point. In the literature, this point in 3D space is indicated as the optical (or lens or camera) center.

**Figure 1.3: The geometry of a pinhole camera as seen from the X2 axis**

Let's try to understand how the coordinates  $(y_1, y_2)$  of point Q depend on the coordinates  $(x_1, x_2, x_3)$  of point P. It is made with the help of Figure 1.3 that marks the same view as Figure 1.2 but now from on top, looking down in negative direction of the X2 axis.

As shown in Figure 1.3, that are two similar triangles, both having parts of the projection line (green) as a hypotenuses. The catheti of the left triangle are  $-y_1$  and  $f$  and the catheti of the right triangle are  $x_1$  and  $x_3$ . These two similar triangles pursue that

$$\frac{-y_1}{f} = \frac{x_1}{x_3} \quad \text{or} \quad y_1 = -\frac{fx_1}{x_3} \quad (1.1)$$

A similar examination, searching in the negative direction of the X1 axis gives

$$\frac{-y_2}{f} = \frac{x_2}{x_3} \quad \text{or} \quad y_2 = -\frac{fx_2}{x_3} \quad (1.2)$$

This can be summarized as

$$\begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = -\frac{f}{x_3} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \quad (1.3)$$

which is an expression that shows the relation between the 3D coordinates  $(x_1, x_2, x_3)$  of point P and its image coordinates  $(y_1, y_2)$  given by point Q in the image plane. It should be attention on that the mapping from 3D to 2D coordinates described by a pinhole camera is a perspective projection followed by a 180 degree rotation in the image plane. This is matched with a real pinhole camera works, the resulting image is turned 180 degree and the relative size of scheduled objects depends on their distance to the focal point and the whole size of the image depends on the distance  $f$  between the image plane and the focused point. To create an unrotated image, that it is expected from the camera, there are two alternative ways:

- In any direction, turn around the coordinate system in the image plane 180 degree. It is a solution any practical performing of a pinhole camera would fix the problem; the image is turned around before looking at it for photographic cameras, and for digital cameras pixel information is sent in such an order that it becomes rotated.
- The image plane  $o$  is put intersects the  $X_3$  axis at  $f$  instead of at  $-f$  and revise the previous calculations. This would generate a virtual (or front) image plane that can't be carried out in practically, but provides a theoretical camera which may be simpler to analyze than the real one.

Either in these cases, the results of mapping from 3D coordinates to 2D view coordinates is given by

$$\begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = \frac{f}{x_3} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \quad (1.4)$$

(similar to Equation 1.3 except no minus sign)

## **1.2. Application Domain**

Pose estimation of a 3D object with respect to a camera – or vice versa – from the object's 2D image(s) is a subtask in robotics, computer graphics, computer and machine vision. It is, for example, used for robot guidance in manufacturing applications. In augmented reality, it is required for accurately inserting computer graphics objects into photographic scenes. In computer vision, pose estimation is instrumental for object recognition. In machine vision, it may sometimes be needed for making precise measurements. And in a variety of tasks, it is used for camera calibration (i.e., finding the pose of camera with respect to the world coordinates) before carrying out the actual task.

## 2. LITERATURE SURVEY

The ideas for optimizing the process of finding a pose from 2D-3D correspondences have been come up by many people. Most of the algorithms are built on a linear or nonlinear system of equations which is required to be solved, however; how these equations are obtained and how many parameters to be estimated is very different. It is not for the same purpose that all algorithms are made, it still is aimed for speed and accuracy in their area.

The hypothesize-and-test approach is the classical one to solving these coupled problems (Grimson 1990). In this approach, a small set of object feature to image feature correspondences are hypothesized, first. The pose of the object is computed, formed on these correspondences. Then, the object points are back-projected into the image using this pose. On condition that the original and back-projected images are amply similar, then the pose is accepted; or, a new hypothesis is formed and the process is repeated. The RANSAC algorithm (Fischler 1981) is perhaps the best known example of this approach, for the condition that no information is available to confine the correspondences of object points to image points. In order to determine a pose, if three correspondences are used, a high possibility of success can be achieved by the RANSAC algorithm in  $O(MN^3 \log N)$  time when there are  $M$  object points and  $N$  image points.

The condition mentioned is here is one of the problems that is encountered when applying a model-based approach to the object recognition problem, and as such has taken considerable attention. (The appearance-based approach (Murase 1995) in which multiple views of the object are compared to the image is the other main approach to object recognition. Yet, as 3D models are not used, this one does not provide accurate object pose.) Many investigators (e.g., (Cass 1994, Cass 1998, Ely 1995, Jacobs 1992, Lamdan 1988, Procter 1997)) approximate the nonlinear perspective projection through linear affine approximations. This is accurate if the relative depths of object features are small compared to the distance of the object from the camera. Baird's tree-pruning method (Baird 1985), with exponential time complexity for unequal point sets, and Ullman's alignment method

(Ullman 1989) with time complexity  $O(N^4M^3 \log M)$  were among the pioneer contributions.

The geometric hashing method (Lamdan 1988) settles an object's identity and pose, using a hashing metric computed from a set of image features. Hereby method can only be applied to planar scenes as the hashing metric must be invariant to camera viewpoint, and as there are no view-invariant image features for general 3D point sets (neither perspective nor for affine cameras) (Burns 1993).

In (DeMenthon 1993), an approach using binary search by bisection of pose boxes in 3 to 4D spaces is proposed, extending the research of (Baird 1985, Cass 1992, Breuel 1992) on affine transforms, yet; it had high-order complexity. The approach by Jurie (Jurie 1999) has been inspired for our work and is within to the same family of methods. An initial volume of pose space is guessed, and the whole correspondences compatible with this volume are first taken into account. The pose volume is then reduced again and again until it can be viewed as a single pose. Boxes of pose space are reduced not only by counting the number of correspondences that are compatible with the box as in (DeMenthon 1993), but also on the basis of the probability of having an object model in the image within the range of poses defined by the box, as a Gaussian error model is performed.

Among the researchers who have denoted the full perspective problem, Wunsch and Hirzinger (Wunsch 1996) formalize the abstract problem in a way akin to the approach advocated here as the optimization of an objective function by combining correspondence and pose constraints. Yet, the correspondence constraints are not represented analytically. Instead, each object feature is matched explicitly to the closest lines of the image features' sight. The closest 3D points on the lines of sight are determined for each object feature, and the pose that takes the object features closest to these 3D points is chosen which allows an easier 3D to 3D pose problem to be solved. The process is reiterated until a minimum of the objective function is obtained.

The object recognition approach of Beis (Beis 1999) uses view-variant 2D image features to index 3D object models. It is performed off-line training to learn 2D feature groupings related with large numbers of views of the objects. After, the on-line recognition stage uses new feature groupings to index into a database of learned object-to-image correspondence hypotheses. These hypotheses are used for pose estimation and verification.

The pose clustering approach to model-to-image registration and the classic hypothesize-and-test approach is similar to each other. All hypotheses are created and clustered in a pose space before any back-projection and testing takes place, instead of testing each hypothesis as it is created. This former step is performed only on poses associated with high-probability clusters. It is of the idea that hypotheses including only correct correspondences should form larger clusters in pose space than hypotheses that include incorrect correspondences. Olson (Olson 1997) gives a randomized algorithm for pose clustering with time complexity  $O(MN^3)$ .

Beveridge and Riseman's method (Beveridge 1992, Beveridge 1995) is also related to DeMenthon's approach. Random-start local search is combined with a hybrid pose estimation algorithm engaging both full/weak-perspective camera models. A steepest descent search in the space of object to-image line segment correspondences is performed. A weak-perspective pose algorithm is used to rank neighbouring points in this search space, and a full-perspective pose algorithm is used to update the object's pose after making shifting to a new set of correspondences. The time complexity of this algorithm was determined empirically to be  $O(M^2N^2)$ .

In (Kanatani, 1985b), a pose parameter estimation is proposed assuming no information on correspondences. Yet, it is assumed by the algorithm that the scene is planar with a closed curve drawn on it under orthographic projection. As the algorithm uses difference to approximate derivatives, it is generally very sensitive to noise. This algorithm has been extended in (Kanatani, 1985a) to be applicable under perspective projection.

In (Lin et al., 1986), a correspondenceless pose estimation algorithm is proposed built on the analysis of the eigenstructure of the scatter matrix.

In (Aloimonos and Herve, 1990), it is a correspondenceless pure translational pose estimation algorithm is proposed which assumes that the z component of the translation vector is much smaller than the depth of the scene. As a result, the author approximates as equal the depths of the same 3D point in different camera centred coordinate frames.

In (Lin et al., 1994), a correspondenceless pose estimation algorithm under orthographic projection is proposed. Three cameras are used by the algorithm and it is based on the eigenstructure analysis of the scatter matrix.

In (Govindu et al. 1998), a correspondenceless pose estimation has been proposed based on the use of the geometric descriptors of a contour. In the experiments, aerial images are used where the 2D contour may be extracted. However, the transformation cannot be guaranteed to be a 2D transformation, so that the usefulness of the algorithm is severely limited.

In (Tarel et al., 1997), a correspondenceless method was proposed to estimate 3D projective transformation parameters. This algorithm uses an iterative method to find the initial estimation first for projective transformation parameters based on bitangent lines and bitangent planes. Then the pose parameters are refining by iteration based on the extended ICP (Iterative Closest Point) algorithm.

In Liu and Rodrigues (2001), a correspondenceless pose estimation algorithm has been induced from a realistic camera setup. The algorithm provides a closed form solution to all parameters of interest. What is important to emphasize is that the algorithm does not require disambiguating multiple solutions which is in contrast with some correspondence-based and correspondenceless pose estimation algorithms (e.g. Fishler and Bolles, 1981; Tsai and Huang, 1984; Lin et al., 1986, 1994; Huang and Netravali, 1994; Tarel et al., 1997).

### **3. FEATURE EXTRACTION**

GPE needs the coordinates of the points that determined as the points of the object model. To give this information to the GPE a feature extraction must be done on the picture.

#### **3.1. MANUAL, SEMI-MANUAL, AND AUTOMATED FEATURE EXTRACTION**

The manual method is the basic method to get the coordinates is using a tool that gives the pixel coordinates and then typing the coordinate to the file which GPE uses it as an input. This method is very simple but it is not useful in terms of time and accuracy.

In semi-manual method, a program should be used to do the job. The program takes the picture as an input and shows it on the screen. When the user clicks mouse on an area in the picture the program writes the coordinates of the pixel to the file that GPE uses.

The most useful method is to automate all the steps. The points on the object that is used for object model are marked by infrared leds. Also an infrared filter is used on the camera which the pictures are taken by. After these, the picture is taken. As shown in Figure 3.1 there can be seen only black and white areas. White regions are formed by the infrared leds and also these regions are points that are needed for GPE. However, there must be an algorithm which is called blob coloring or contour tracing to make the white regions meaningful. Using the blob coloring algorithm the centers of mass of the white regions can be find. Finally these parameters can be used by GPE as input.

**Figure 3.1: Image that is taken using infrared leds and infrared filter**

### **3.2. TRADE-OFFS IN BLOB COLORING**

Blob coloring scans an image and groups its pixels into blobs based on pixel connectivity, *i.e.* all pixels in a blob share similar pixel intensity values and are in some way connected

**Figure 3.2 : L-shaped template for blob coloring**

with each other. It can be seen in Figure 3.2 briefly. Once all groups have been determined, each pixel is labeled with a graylevel or a color (color labeling) according to the blob it was assigned to.

Extracting and labeling of various disjoint and connected blobs in an image is central to many automated image analysis applications. The applications use several algorithms. The efficiency of these algorithms are appears in big images or complex images. There are six algorithms explained in below. The most efficient one in literature is Main Color Emphasized Blob Coloring Algorithm. Because it scans the whole image only once. In contrast, the other algorithms have to scan the image twice.

### **3.2.1. Rosenfeld and Pfaltz's Algorithm**

The first method which is suggested by Rosenfeld and Pfaltz carries out two passes over a binary image. Each point is encountered once in the first pass. A further study of its four neighbouring points (left, upper left, top, and upper right) is conducted at each black pixel  $P$ . If none of these neighbours carries a label, then  $P$  is allocated a new label. In other ways, those labels carried by neighbours of  $P$  are said to be equivalent. In this occasion, the label of  $P$  is replaced by the minimal equivalent label. For this resolution, a pair of arrays; one containing all current labels and the other the minimal equivalent labels of those current labels, is generated,. In the second pass, label substitutes are made.

### **3.2.2. Haralick's Algorithm**

Haralick designed a method to remove the excess storage required for the pair of arrays which are suggested in the first method. Each black pixel is given a unique label, first. The labelled image is then processed iteratively in two directions. Each labelled point is reassigned the smallest label among its four neighbouring points in the first pass, administered from the top down,. The second pass is similar to the first, except that it is administered from the bottom up. The process goes on iteratively until no more labels change. The memory storage of hereby method is small, yet; the overall processing time differs according to the complexity of the image being processed.

### **3.2.3. Lumia's Algorithm**

In the method put up by Lumia et al. which compromises between the two preceding methods, labels are assigned to black pixels in the first top-down pass as in the first method. However, the labels on this line are adjusted to their minimal equivalent labels at the end of each scan line,. The second pass begins from the bottom and works similarly as the top-down pass which can be proven that all components obtain a unique label after these two passes.

### **3.2.4. Fiorio and Gustedt's Algorithm**

A special model of the union-find algorithm was activated by Fiorio and Gustedt, that it runs in linear time for the component-labeling problem. This methodology is made up of two passes. In first one, each set of corresponded labels is described as a tree. And a re-labeling progress is performed in the second pass. To combine two trees into a single tree, this operation is used in the union-find methods serves, when a node in one tree bears an 8-connectivity relations to a node in the other tree.

### 3.2.5. Shima's Algorithm

Shima offered this method et al. is specifically fit for compressed images in which a procedure before processing as required to reform image elements into runs. An examining part and a propagation step are practiced frequently on the run data. In the examination part, the image is countered till an unlabeled run (referred as a focal run) is found and is allocated a new label. In the propagation step, the label of each focal run is produced to adjacent runs above or below the scan line.

### 3.2.6. Main Color Emphasized Blob Coloring

Main Color Emphasized Blob Coloring Algorithm (MCEBC) quantizes the colors into the predefined color classes, using the heuristic information that humans tend to emphasize the dominant color component when they perceive and memorize colors. The experimental results indicate that the method approximates the user's classification better than the other methods that use the mathematical color difference formulas. The MCEBC algorithm is implemented in a content-based image retrieval system, called QBM system. The retrieval results of the system using MCEBC algorithm is quite satisfactory and shows higher success rates than using other methods.

### 3.2.6. Proposed Blob Coloring Algorithm

There are six major algorithms in literature. The most efficient of them is the MCEBC algorithm. However, using simple images it is not needed to use the MCEBC. In addition to this, in the next section it has been seen that in simple images, Rosenfeld and Pfaltz's algorithm is relatively faster than MCEBC. So Rosenfeld and Pfaltz's algorithm is used in the blob coloring part of the thesis. The algorithm can be seen below.

Let the initial color,  $k=1$ . Scan the image from left to right and top to bottom.

```
If  $f(xC) = 0$  then continue
else
  begin
    if ( $f(xU) = 1$  and  $f(xL) = 0$ )
      then color  $(xC) :=$  color  $(xU)$ 
```

```

if ( $f(xL) = 1$  and  $f(xU) = 0$ )
    then color ( $xC$ ): = color ( $xL$ )

if ( $f(xL) = 1$  and  $f(xU) = 1$ )
    then begin
        color ( $xC$ ): = color ( $xL$ )
        color ( $xL$ ) is equivalent to color ( $xU$ )
    end

comment: two colors are equivalent.

If( $f(xL) = 0$  and  $f(xU) = 0$ )
    then color ( $xC$ ): =  $k$ ;  $k := k + 1$ 

comment: new color
end

```

### 3.2.7. Blob Coloring Results

As always done there should be chosen a method to do the blob coloring efficiently. To make this Rosenfeld and Pfaltz's algorithm and MCEBC are tested with same photos. As it was told above, the MCEBC algorithm is the best blob coloring algorithm in literature. However, because of using the infrared leds and infrared filters, the taken photos become simpler. This reason effects the run-times positively especially the Rosenfeld and Pflatz method. In Table 3.1 the run-time results can be seen. Two of the methods find the blobs very quickly.

**TABLE 3.1 Results of Blob Coloring Algorithms**

	<b>Rosenfeld (ms)</b>	<b>MCEBC (ms)</b>
<b>1</b>	0.312500	0.312500

<b>4</b>	0.312500	0.468750
<b>5</b>	0.312500	0.468750

## 4. GRAVITATIONAL POSE ESTIMATION

Gravitational Pose Estimation (GPE) is a correspondenceless method which is inspired by classical mechanics. GPE can handle occlusion and uses only one image (i.e., perspective projection). GPE creates a simulated gravitational field from the image and lets the object model move and rotate in that force field, starting from an initial pose.

### 4.1. PROBLEM FORMULATION

Image of a 3D point (on the image sensor of a regular camera) is the perspective projection of the point on to the image plane – though less accurate approximations (e.g. orthographic projection) are possible. If the coordinates of the point are  $(x, y, z)$  with respect to the camera coordinate frame (origin is the camera lens' center and the X-Y axes are along the edges of the rectangular image sensor), then its image is located at  $(x.f/z, y.f/z, f)$  where  $f$  is the distance between the camera lens and image plane – called  $f$  because it is approximately equal to the focal length of the lens. In real life, image plane is behind the camera lens at  $z = -f$  and image is inverted. However, most treat it as if the image plane is at  $z = f$  without any loss of generality – a simple flip of all three coordinates does the job. All points on line  $(kx, ky, kz)$ , where  $k$  is a free parameter, produce the same image point on the image plane. Therefore, for each image point, it can be constructed a unique line in 3D (called *line of sight*) on which the object point must be located.

A camera image does not consist of feature points; instead it consists of pixels, each of which is assigned a value indicating brightness and color if any. However, it is possible to transform an image to a collection of feature points by computer vision techniques. Each of the feature points on the image plane corresponds to a point on the object and gives us a line of sight (LOS) in 3D when extended through the lens center. Thus, from the image of an object a *pencil of lines* is obtained, and it is known that they go through the object as in Figure 4.1.

**Figure 4.1: An object in the gravitational field of the lines of sight**

Source : H. Fatih Ugurdag, Sezer Gören and Ferhat Canbay, 2008. *Correspondenceless pose estimation from a single 2D image using classical mechanics*. October 2008.

GPE (and similar techniques) require a rigid object model, which is a set of 3D *object points* (i.e., feature points) expressed by their coordinates in the *object coordinate frame*. Then, the answer to the pose estimation problem is the pose where the object points are as close to the LOSes as possible. From the above discussion an *energy function* can be devised, which is expected to be *zero* when the correct pose is found. Below are the steps to calculate the **energy** of a suggested pose for the object:

- For the suggested pose, **transform object points'** coordinates in the object model from the object coordinate frame to the camera coordinate frame. (Everything from this point on is computed in the camera coordinate frame.)
- Construct the **LOSes** from the image points.
- Let  $d_{ij}$  be the shortest, hence perpendicular **distance**, between the  $i^{\text{th}}$  point of the object model and the  $j^{\text{th}}$  LOS. Calculate and sort all  $d_{ij}$ 's in ascending order. Place them in a list called *DistanceList*.
- **Pair the LOSes with object points** until there is no LOS left (assuming no false feature points). Do this in such a way that an object point is paired with only one LOS and an LOS is paired with only one object point. Start with the smallest  $d_{ij}$  (the topmost

element in *DistanceList*), and assign the  $i^{\text{th}}$  point of the object model to the  $j^{\text{th}}$  LOS. Erase all distances in *DistanceList* that belong to object point  $i$  (all  $d_{ik}$  where  $k$  is a free parameter) as well as all distances that belong to LOS  $j$  (all  $d_{kj}$  where  $k$  is free). Continue with the smallest  $d_{mn}$  in the updated *DistanceList*, and pair object point  $m$  and LOS  $n$ . Continue until all LOSes are paired.

- Calculate the energy of object model in the suggested pose, which is equal to the sum of squares of the distances between all LOS-object point pairs:

$$E = \sum d_{ij}^2. \quad (4.1)$$

It should be noted that one can calculate the average distance between the points and lines as in:

$$d_{ave} = \sqrt{(E / \# \text{lines})} \quad (4.2)$$

When the estimated (suggested) pose is equal to the correct pose,  $d_{ave}$  should be quite small with respect to the dimensions of the object. Although this is currently our criterion, a maximum feature distance criterion may also be imposed.

## 4.2. OVERALL APPROACH

The algorithm starts by forming the LOSes. A line can be represented (though not canonically) by a point on it and a (unit-length) direction vector. As the object points are wanted to coincide with the LOSes, it is quite intuitive to form a gravitational field where LOSes attract object points as shown in Figure 4.1. Since is not wanted object points to move after they reach the LOSes, it makes sense to make the force (gravitational field) proportional to the distance between object points and LOSes. The outline of the algorithm is as follows:

- 1) Pair the object points and LOSes on a 1-to-1 basis as described in Section 4.1 in the

energy calculation instructions.

- 2) Calculate the force on each object point through equation (4.3), where  $\vec{f}_i$  is the force on object point  $i$  and  $d_{ij}$  is the distance between the  $i^{\text{th}}$  object point and its paired LOS  $j$ , and  $\hat{r}_{ij}$  is the unit vector that points from point  $i$  to line  $j$  and is perpendicular to line  $j$ .

$$\vec{f}_i = d_{ij} \hat{r}_{ij} \quad (4.3)$$

- 3) Use classical mechanics to calculate the translational,  $\vec{a}_t$ , and rotational acceleration,  $\vec{a}_r$ , as follows:
  - a) Calculate effective force,  $\vec{f}_{cm}$  applied to the object's center of mass (COM) by:

$$\vec{f}_{cm} = \sum_i \vec{f}_i. \quad (4.4)$$

Note that force on an unpaired object point (a possibly occluded point) is zero. However, unpaired points still contribute to the COM calculations, i.e., they are still considered part of the object.

- b) Calculate translational acceleration,  $\vec{a}_t$ , which is the acceleration of object's COM, by (4.5), where  $m_{tot}$  is the total mass of the object. (Normally, it is assumed every feature point has a mass of 1. However, if there are different degrees of certainty in feature extraction or there are reasons to believe that some feature points have to be aligned more carefully with LOSes, then those points may be assigned a larger mass than other points.)

$$\vec{a}_t = \vec{f}_{cm} / m_{tot} \quad (4.5)$$

- c) Calculate total torque,  $\vec{t}_{cm}$ , around the COM using the summation of cross-products in (4.6), where  $(\vec{r}_{cm})_i$  is the vector that gives the relative displacement of point  $i$  with respect to COM.

$$\vec{t}_{cm} = \sum_i (\vec{r}_{cm})_i \times \vec{f}_i \quad (4.6)$$

- d) Calculate the rotational inertia matrix of the object (at the current pose,)  $\mathbf{R}$ , through (4.7), where  $(\mathbf{R})_{pq}$  is a component of matrix  $\mathbf{R}$  that is located in row  $p$  and column  $q$ ,  $m_i$  is the mass of object point  $i$ , and  $((\vec{r}_{cm})_i)_k$ ,  $((\vec{r}_{cm})_i)_p$ , and  $((\vec{r}_{cm})_i)_q$  denote the  $k^{\text{th}}$ ,  $p^{\text{th}}$ , and  $q^{\text{th}}$  components of the vector  $(\vec{r}_{cm})_i$  respectively.

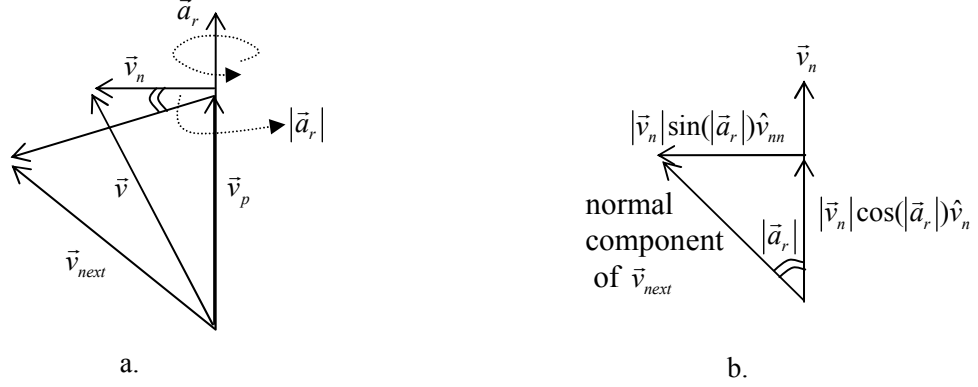

$$(\mathbf{R})_{pq} = \sum_i m_i \sum_k \{((\vec{r}_{cm})_i)_k ((\vec{r}_{cm})_i)_k - ((\vec{r}_{cm})_i)_p ((\vec{r}_{cm})_i)_q\} \quad (4.7)$$

- e) Calculate angular acceleration,  $\vec{a}_r$ , using (4.8), where  $\mathbf{R}^{-1}$  is the inverse of rotational inertia matrix,  $\mathbf{R}$ .

$$\vec{a}_r = \mathbf{R}^{-1} \vec{t}_{cm} \quad (4.8)$$

- 4) Let the pose of object be expressed by vectors  $\vec{n}$ ,  $\vec{s}$ ,  $\vec{a}$  (unit vectors by definition) and  $\vec{p}$ , where  $\vec{n}$  is the orientation of X-axis of the object model (object coordinate frame) expressed in the camera coordinate frame,  $\vec{s}$  is the orientation of Y-axis,  $\vec{a}$  is the orientation of Z-axis, and  $\vec{p}$  is the position of object. Then:

- a) Calculate  $\Delta\vec{p}$  where  $\Delta\vec{p} = \vec{a}_r$  and  $\Delta\vec{p}$  is the change in  $\vec{p}$ , so add  $\Delta\vec{p}$  to old  $\vec{p}$  to get the new  $\vec{p}$ .
- b) Rotate  $\vec{n}$ ,  $\vec{s}$ , and  $\vec{a}$  around the vector  $\vec{a}_r$  by an angle equal to  $|\vec{a}_r|$  radians, where  $|\vec{a}_r|$  denotes the length of the vector  $\vec{a}_r$ . In order to do this, we follow the steps below for each of  $\vec{n}$ ,  $\vec{s}$ , and  $\vec{a}$ :

**Figure 4.2. Calculation of  $\vec{v}_{next}$  . a. 3D view b. Top view**  
 Source : H. Fatih Ugurdag, Sezer Gören and Ferhat Canbay, 2008. *Correspondenceless pose estimation from a single 2D image using classical mechanics*. October 2008.

Let  $\vec{v}$  be a vector to be rotated around  $\vec{a}_r$ , shown as in Figure 4.2. Normalize  $\vec{v}$  (i.e., make it unit-length) to get unit vector  $\hat{v}$ . Identify the two components of  $\hat{v}$ ,  $\hat{v}_p$  and  $\hat{v}_n$ , where  $\hat{v}_p$  is parallel to  $\vec{a}_r$ , and  $\hat{v}_n$  is normal (i.e., perpendicular) to  $\vec{a}_r$ , using normalization, dot-product, and scalar multiplication in (4.9) and vector subtraction (4.10).

$$\vec{v}_p = (\hat{a}_r \cdot \hat{v}) \hat{a}_r \quad (4.9)$$

$$\vec{v}_n = \vec{v} - \vec{v}_p \quad (4.10)$$

- i) Construct unit vector  $\hat{v}_{nn}$  from  $\hat{v}_n$  using (4.11). Vector  $\hat{v}_{nn}$  is normal to plane  $\hat{v}_n$  and  $\vec{a}_r$ , and is the direction vector  $\vec{v}$  moves when it is rotated around  $\vec{a}_r$ .

$$\vec{v}_{nn} = \hat{a}_r \times \hat{v}_n \quad (4.11)$$

- ii) Calculate the next  $\vec{v}$  denoted as  $\vec{v}_{next}$  using (4.12):

$$\vec{v}_{next} = \vec{v}_p + |\vec{v}_n| (\cos(|\vec{a}_r|) \hat{v}_n + \sin(|\vec{a}_r|) \hat{v}_{nn}) \quad (4.12)$$

**Figure 4.3: Four different views of a 10-point synthetic object (3 of the points are collinear)**

Source : H. Fatih Ugurdag, Sezer Gören and Ferhat Canbay, 2008. *Correspondenceless pose estimation from a single 2D image using classical mechanics*. October 2008.

- 5) Calculate the energy  $E$  at the next pose – pair object points and LOSes – use (4.1). If the energy obtained is not small enough, go to step 2 and continue to move the object in the gravitational field until it gets stuck in a locally minimum energy state. If it is stuck, then update the minimum pose and energy, provided current one is the best. If the energy is still not small enough (and the maximum number of iterations is not reached,) then go to step 6 to shake the object (*shake* means a random rotation).
- 6) Generate an angular acceleration,  $\vec{a}_r$ , randomly. Apply step 4 to calculate the next orientation. Then go to step 1.

As an example, a 10-point object is shown in Figure 4.3. GPE has been run by taking the true pose as

$$\vec{n} = (1, 0, 0), \vec{s} = (0, 1, 0), \vec{a} = (0, 0, 1), \vec{p} = (0, 0, 5)$$

and initial pose as

$$\vec{n} = (0, 1, 0), \vec{s} = (0, 0, 1), \vec{a} = (1, 0, 0), \vec{p} = (20, 20, 20).$$

**Figure 4.4: Trajectory of the above object during GPE's search for the true pose.**

Source : H. Fatih Ugurdag, Sezer Gören and Ferhat Canbay, 2008. *Correspondenceless pose estimation from a single 2D image using classical mechanics*. October 2008.

The initial energy came out to be around 8,000. The criterion for a local minimum was set such that the absolute change in the energy is less than 0.0001 for 30 consecutive iterations. The criterion for termination was either getting an energy of less than 0.0002 or to reaching iteration 1,000. (For our larger set of experiments, it has been used up to 50,000 iterations since GPE runs quite fast.) The result of this initial experiment was impressive. The number of shakes was only 2. The program stopped with energy less than 0.0002 after the 215<sup>th</sup> iteration. The trajectory of the object during the program execution is plotted in Figure 4.4. In addition, energy versus iteration count is given in Figure 4.5.

### 4.3. GPESoftPOSIT

GPESoftPOSIT is an integration of the two algorithms, GPE and SoftPOSIT. The main idea here is to run SoftPOSIT with an initial guess that is close to the true pose instead of trying any random starts. The pose found by GPE is taken as the initial guess for the object's when running SoftPOSIT. Whenever the ratio of object points matched to LOSes to the total number of object points reaches a predetermined criterion (here it is set to 0.7) and also SoftPOSIT satisfies its own definition of convergence, then SoftPOSIT terminates and outputs the guess for the object's pose. If SoftPOSIT is unable to find a pose, then the initial guess for the object's pose (the result of GPE) is presented as the output.

SoftPOSIT has a parameter, called  $\beta_0$ , which corresponds to the fuzziness of the correspondence matrix. If the initial pose is close to the actual pose, then  $\beta_0$  should be around 0.1. In our case, since our initial pose comes from GPE and it is known that it is close to the actual pose, it is set  $\beta_0$  to 0.1. As an exercise, the 10-point synthetic object in Figure 4.3 and its image for a given pose were constructed. Using the object model and image, GPE was run and its result was piped to SoftPOSIT. The projected model and the original image are shown in blue and red, respectively in Figure 4.6a through 4.6e. The projected model shown in Figure 4.6a corresponds to the object at the pose found by GPE. The iterations of SoftPOSIT, on the other hand, are shown in Figure 4.6b through 4.6e.

**Figure 4.6: Converging to optimum using GPEsoftPOSIT.**

**b. c. d. e. f.** Iterations of SoftPOSIT to improve the pose.

#### 4.4. TRADE-OFFS IN POINT-LINE MATCHING

The most important part of the GPE algorithm is the matching the points with lines accurately. Key point is the distances between point and lines. If the total value of the distances after matching equals zero, the perfect matching is found. However, in real life this result can not be found zero. So the results are approximately zero. There are various type of algorithms to match points and lines but two of them are compared and better one is used.

##### 4.4.1. Regular Method

In this method a matrix is used to for the distances between points and lines. In addition to this, two lists are used for the unmatched points and lines. And also an array is used for matched items as matching table. Let's call for unmatched points  $Ind\_P$ , for unmatched lines  $Ind\_L$ , for the matching table  $A$  and the distances between points and lines will be hold in matrix  $M$ .

- The algorithm finds the minimum distance in  $M$  and keeps the index of it. While scanning the  $M$  the algorithm looks for the unmatched index using  $Ind\_P$  and  $Ind\_L$ .
- After finding the minimum value, the algorithm deletes the index value of matched point and line from  $Ind\_P$  and  $Ind\_L$  and keeps the values in  $A$ .
- The index of  $A$  is used for lines and the value in this index is used for index of point. This process ends when  $Ind\_P$  becomes empty.

As in the below, algorithm simulated on four points and four lines. The initial values used in algorithm can be seen in Figure 4.7.

<b>0</b>	<b>1</b>	<b>2</b>	<b>3</b>

**A**

<b>L2</b>	2	1	0	3
<b>L3</b>	0	1	2	3

**M**

**Figure 4.7 : The initial values of the elements before the algorithm starts**

The first step of the algorithm can be seen in Figure 4.8. Minimum distance is found in index L0-P3 of matrix M and this matching is assigned on A. After these, L0 is deleted from Ind\_L and P3 is deleted from Ind\_P.

In the second step of the algorithm, the minimum value is searched in a smaller part of the M. In Figure 4.9 it is shown using coloring. Gray colored cells are matched in previous step and the white cells are available for searching. After searching the available points and lines it is found that the minimum distance is in the index P1-L1. 1 is recorded in index 1 of A. P1 is removed from Ind\_P and L1 is removed from L1.

L2	2	1	0	3
L3	0	1	2	3

**Matrix M**

**Figure 4.11 : The situation of the elements after the algorithm runs**

After searching the M, the minimum value is found in L2-P2. Again, doing same processes above, P2 and L2 are matched and they are removed from the available ones as shown in Figure 4.10.

As it can be seen in Figure 4.11 last step of the algorithm is the simplest step. Because there is only one point and one line. They are matched without searching and matching table is filled fully.

#### **4.4.2 Sorting Based Method**

In the sorting based method two one-dimensional arrays are used instead of a matrix. First one is used to keep the Line-Point information (LP) and the second one is used to keep the distances (D).

- The algorithm begins with sorting the second array smaller to the greater distance. When a swap process is done, the same process is done on array LP too.
- After sorting the arrays the first element of the arrays are match to each other and the matched line and point's indicies are marked.
- In the other steps it matches the first unmarked point-line and marks the indicies that these point and line have. The algorithm is simulated below.

As shown in Figure 4.12, values of the matrix used in regular method is also used in sorting based method. The values are inserted to the one-dimensional array row by row.

	P0	P1	P2	P3

**Figure 4.13 : First Step of the Algorithm**

In the first step array D is sorted from smaller to bigger. As it can be seen in Figure 4.13, array LP changes at the same time D.

The algorithm starts to match the points and lines by the end of sorting step. The first element of the array D is the minimum. So it is matched to each other and its background is colored red in Figure 4.14. The zero index of A is assigned 3, because of being matched with P3.

**Figure 4.14 : Second Step of the Algorithm**

In the second step L0 and P3 were matched. In Figure 4.15 the background of the related elements of array LP and D are colored gray. The algorithm finds the first uncolored element. It is the second element of D and L1 and P1 are matched with each other. Its background is colored red in Figure 4.15 like the second step. After these, P1 is written on index one of the array A.

#### 4.4.3. Point-Line Matching Results

There were used two different point-line matching algorithm which are called regular method and sorted-based. For comparing the two algorithms six different data fed as input to algorithms. Number of points and lines feeded from smaller to greater. As it can be seen in Table 4.1 below they finds the results in the same time when the data is smaller. However, when the data become bigger the regular method gets the result faster. Also in Figure 4.18, runtimes are shown on a graphic.

**TABLE 4.1 : Runtime comparison of the point-line matching algorithms**

<b>Number of Points-Lines</b>	<b>Regular Method (ms)</b>	<b>Sorting Based Method (ms)</b>

## 5. GRAVITATIONAL POSE ESTIMATION EXPERIMENTS

GPE has been first validated using real images, and then GPE, GPEsoftPOSIT, and random start SoftPOSIT has been compared on synthetic data with and without occlusion.

### 5.1. RESULTS WITH REAL IMAGES

In this section, GPE is tested (without SoftPOSIT) with real images taken by a simple webcam, and our results are still impressive. (A webcam or any other cheap camera has a fish-eye effect. Please notice that the A4 paper's borders in Figure 5.1 look curved.) There is a fixture used in experiments (see Figure 5.2) where an object can be attached, rotate the object by means of an arm, and adjust the angle manually. As there is a protractor attached to the arm, it is exactly known what the actual angle is. In Figure 5.1, the images of a black polygon are taken when the object is brought to angles  $70^\circ$ ,  $75^\circ$ ,  $80^\circ$ ,  $85^\circ$ ,  $90^\circ$ ,  $95^\circ$ ,  $100^\circ$ ,  $105^\circ$ , and  $110^\circ$  on the protractor. All of the images taken are shown in Figure 5.1a through 5.1i.

Although GPE can measure all 6 degrees of freedom of a 3D pose, it is hard to measure the same 6 degrees of freedom mechanically as it requires a very fancy apparatus. Instead there is a simple mechanical fixture where it can be measured one degree of freedom (a rotation angle) with great precision. From GPE it is received two 3D poses and compare them to find the rotation angle and then compare it with the angle read from the fixture's protractor. Note that the plane that the arm traverses when rotated (i.e., the plane of the protractor) and plane of the A4 sheet (where the polygon is drawn) are the same.

**Figure 5.2 : The fixture used for the real image experiment**

In the real image experiment, the object model contains corners of the polygon. The feature extraction has been done manually by pointing to the corners of the polygon with the mouse and reading the coordinates by means of image viewing software. The object coordinate frame is defined by the A4 sheet. The Z-axis is orthogonal to the sheet and the X and Y axes are along the edges of the sheet. The directions of the X, Y, Z axes of the object model are expressed respectively by  $\vec{n}$ ,  $\vec{s}$ , and  $\vec{a}$  in the camera coordinate frame.

To evaluate the accuracy of GPE, the relative angle between every image pair was measured by both GPE and protractor. The results of this experiment are given as a chart in Figure 5.3. In the chart, ACTUAL2 (horizontal) axis denotes the angle value for image 2, whereas the numbers next to word “vs” denotes the protractor angle for image 1. After running GPE twice, the difference between the two angles is computed. ESTIMATED2 (vertical) axis in Figure 5.3 is the angle estimated for image 2 by GPE. That is, in fact, the difference estimated by two runs of GPE ( $\theta$ ) plus the angle of image 1 from the protractor.

8 groups of image pairs are included in Figure 5.3:

- vs 70: Image 1 at 70° versus image 2 at {75°, 80°, 85°, 90°, 95°, 100°, 105°, 110° }.
- vs 75: Image 1 at 75° versus image 2 at {80°, 85°, 90°, 95°, 100°, 105°, 110° }.
- vs 80: Image 1 at 80° versus image 2 at {85°, 90°, 95°, 100°, 105°, 110° }.

- vs 85: Image 1 at 85° versus image 2 at {90°, 95°, 100°, 105°, 110° }.
- vs 90: Image 1 at 90° versus image 2 at {95°, 100°, 105°, 110° }.
- vs 95: Image 1 at 95° versus image 2 at {100°, 105°, 110° }.
- vs 100: Image 1 at 100° versus image 2 at {105°, 110° }.
- vs 105: Image 1 at 105° versus image 2 at 110°.

105°	60	15.6
110°	63	21.3

Source : H. Fatih Ugurdag, Sezer Gören and Ferhat Canbay, 2008. *Correspondenceless pose estimation from a single 2D image using classical mechanics*. October 2008.

Absolute estimation error (GPE minus protractor) is presented in Figure 5.4 in degrees. The average absolute error for the 36 image pairs is 0.43°. Table 5.1 is also presented where the run-time of the pose estimation algorithm and the number of shakes for the 8 experiments where image 1 is at 70°, and image 2 is varied between 75°-110°.

All of the experiments were carried out on a laptop running Cygwin (i.e., Linux emulator in Windows) with a 1.6 GHz Pentium processor and 1GB RAM. The images that used in this experiment have coplanar points. Since SoftPOSIT requires at least 4 non-coplanar points, GPEsoftPOSIT has been unable to utilized in this real image experiment. However, it had been put together an extensive set of synthetic test images to evaluate random start SoftPOSIT, GPEsoftPOSIT, and GPE.

### 5.1.1. Mechanics and Electronics Aspects

In this thesis, it has been used very simple and useful tools have been used to get results. As it is explained in Section 5.1 and shown in Figure 5.2 a mechanical fixture is used to measure the angle. The pictures are taken with a simple webcam. GPE is run on a Pentium IV machine which has a 1GB memory. After testing GPE with these real images and being succesful, to automate the process it is has been used infrared leds and an infrared filter in front of the camera.

### 5.1.2. Computing the Relative Angle

To estimate the relative angle of the object in an image with respect to another image, GPE is run twice. We take vectors  $\vec{n}_1$ ,  $\vec{s}_1$ , and  $\vec{a}_1$  estimated by GPE for the 1<sup>st</sup> image and  $\vec{n}_2$ ,  $\vec{s}_2$ , and  $\vec{a}_2$  for the 2<sup>nd</sup> image. Then it is possible to calculate the rotation angle (denoted as  $\theta$ ) using equations (5.1), (5.2), and (5.3), when the plane of the A4 sheet is identical to the plane of the protractor's rotation plane – as in this case.

$$\theta_n = \text{acos}(\vec{n}_1 \cdot \vec{n}_2) \quad (5.1)$$

$$\theta_s = \text{acos}(\vec{s}_1 \cdot \vec{s}_2) \quad (5.2)$$

$$\theta = \frac{\theta_n + \theta_s}{2} \quad (5.3)$$

## 5.2. RESULTS WITH SYNTHETIC IMAGES

In this section, results of GPEsoftPOSIT are shown and compare them with GPE and random start SoftPOSIT, using 3 randomly generated objects with 6, 10, and 15 vertices. For each object, 10 different orientations and positions were generated (using step 1 below) for each configuration. It has been used up to  $3 \times 4 = 12$  configurations (relative distance=3, 7, 10; number of points occluded=0, 1, 2, 3) with each object model.

The ratio of the distance of the object from the lens center (i.e., magnitude of the position vector) over the diameter of the object is what it is called “relative distance.” Note that relative distance is also roughly the reciprocal of the “viewing angle” of the object in radians. Viewing angle is the top angle of the “pencil of lines” from the lens center to the object (Figure 4.1).

In order to calculate the radius of an n-point object, first the centroid is computed (also COM if all points have equal mass) of the object (denoted by  $\bar{c}$ ). Then the squares of distances from object points (denoted by  $\bar{x}_k$  for object point  $k$ ) are sum to the centroid. Then the average is taken followed by a square-root. Hence, the object radius is, in a way, a mean object point distance from the centroid – or more accurately an rms (root-mean-square) displacement from the centroid – see (5.5).

$$relative\_distance = \frac{|\vec{p}|}{2 \cdot object\_radius} \quad (5.4)$$

$$object\_radius = \sqrt{\frac{\sum_{k=1}^n |\bar{x}_k - \bar{c}|^2}{n}} \quad (5.5)$$

The two steps below outline synthetic image creation process in thesis:

1) *True pose generation*: A rotation matrix,  $\mathbf{R}_{\alpha\beta\delta}$  is generated, using random angles  $\alpha$ ,  $\beta$ , and  $\delta$  between  $[-\pi, \pi]$  by

$$\mathbf{R}_{\alpha\beta\delta} = \mathbf{R}_\alpha \mathbf{R}_\beta \mathbf{R}_\delta = \begin{bmatrix} n_x & s_x & a_x \\ n_y & s_y & a_y \\ n_z & s_z & a_z \end{bmatrix} \quad (5.6)$$

$$\mathbf{R}_\alpha = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \alpha & -\sin \alpha \\ 0 & \sin \alpha & \cos \alpha \end{bmatrix} \quad (5.7)$$

$$\mathbf{R}_\beta = \begin{bmatrix} \cos \beta & 0 & \sin \beta \\ 0 & 1 & 0 \\ -\sin \beta & 0 & \cos \beta \end{bmatrix} \quad (5.8)$$

$$\mathbf{R}_\delta = \begin{bmatrix} \cos \delta & -\sin \delta & 0 \\ \sin \delta & \cos \delta & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (5.9)$$

where  $\mathbf{R}_\alpha$  shows the rotation about X-axis,  $\mathbf{R}_\beta$  rotation about Y-axis, and  $\mathbf{R}_\delta$  rotation about Z-axis. Then a random position vector  $\vec{p}$  with a length of  $2 \cdot \text{relative\_distance} \cdot \text{object\_radius}$  is generated.

2) *Image Construction*: With 3D object points in the object model and the true pose parameters, the coordinates of every object point are computed with respect to the camera coordinate frame ( $\vec{v}_c$ ) using the transformation  $\vec{v}_c^T = \vec{v}_o^T \mathbf{R}_{\alpha\beta\delta} + \vec{p}$ , where  $\vec{v}_o$  is the coordinates of the object point in the object coordinate frame and superscript of  $T$  indicates transposed, hence, row vectors. Finally, object points are projected on to the 2D image plane.

For each configuration of each object model, 10 images had been constructed – each at a different and random pose. Then, the performance of GPE had been evaluated, random start SoftPOSIT, and GPEsoftPOSIT by comparing the absolute deviation of each method from the true pose.

For random start SoftPOSIT, SoftPOSIT has been run 500 times with each test image. Whenever the fraction of the number of 3D to 2D matched points is greater than 0.7 and SoftPOSIT is able to converge to a pose, random start SoftPOSIT terminates and outputs the guess for the pose of the object. On the other hand, if no convergence is achieved even after 500<sup>th</sup> run, the random start SoftPOSIT algorithm is terminated. In random start SoftPOSIT, since it is not known whether the randomly generated initial pose is close to the true pose, the parameter  $\beta_0$  of SoftPOSIT is set to 0.0001 enabling that all possibilities of correspondence are possible in the beginning.

To test GPEsoftPOSIT algorithm, SoftPOSIT is run only once using the pose that is output by GPE as the initial pose. In GPEsoftPOSIT, the parameter  $\beta_0$  is set to 0.1 since it is known that the initial pose is close to the actual pose. If the fraction of the number of 3D to 2D matched points is greater than 0.7 and SoftPOSIT is able to converge to a pose, then it outputs the improved guess for the pose of the object. If it fails to get convergence, then the initial pose, which is the result of GPE, is presented as the output. (A predetermined initial pose is used for GPE whether it is used stand-alone or as part of GPEsoftPOSIT.)

If the true pose of the object is expressed by vectors  $\vec{n}$ ,  $\vec{s}$ ,  $\vec{a}$ , and  $\vec{p}$ , and the estimated pose is expressed by vectors  $\vec{n}_G$ ,  $\vec{s}_G$ ,  $\vec{a}_G$ , and  $\vec{p}_G$ , the orientation errors,  $\Delta\theta_n$ ,  $\Delta\theta_s$ , and  $\Delta\theta_a$  and the relative position error,  $\varepsilon_p$  are calculated using the following equations:

$$\Delta\theta_n = \text{acos}(\vec{n} \cdot \vec{n}_G) \quad (5.10)$$

$$\Delta\theta_s = \text{acos}(\vec{s} \cdot \vec{s}_G) \quad (5.11)$$

$$\Delta\theta_a = \text{acos}(\vec{a} \cdot \vec{a}_G) \quad (5.12)$$

$$\varepsilon_p = \frac{|\vec{p}_G - \vec{p}|}{2 \cdot \text{object\_radius}} \quad (5.13)$$

The results of GPE, GPEsoftPOSIT, and random start SoftPOSIT are presented in Table 5.2, Table 5.3 and Table 5.4 where a total of 30 different configurations are shown. For each configuration, there are 10 different tests (i.e., images). Hence, the total number of experiments is 300. The averages of orientation errors ( $\Delta\theta_n$ ,  $\Delta\theta_s$ , and  $\Delta\theta_a$ ) and average of relative position errors ( $\varepsilon_p$ ) obtained from the 10 tests for each configuration are listed in Table 5.2, Table 5.3 and Table 5.4 as  $\overline{\Delta\theta_n}$ ,  $\overline{\Delta\theta_s}$ , and  $\overline{\Delta\theta_a}$  in degrees and  $\overline{\varepsilon_p}$  in multiples of the object diameter.

Random start SoftPOSIT was unable to converge to a pose in 257 tests out of 300 (see the rightmost column in Table 5.2 titled #fails). Having a number listed there does not mean random start SoftPOSIT converged to a pose in all cases. A row in Table 5.2 reports average numbers for the corresponding configuration out of the tests that converged.

On the other hand, GPE (and hence GPEsoftPOSIT) is an algorithm that does not have convergence problems. Hence, it converged in all of the 300 tests. It produced good results in all experiments except the 6/1 (#object points/#occluded points) case. However, note that random start SoftPOSIT was not able to converge even in the 6/0 case. GPE and GPEsoftPOSIT worked fine in 6/0 case. Since acceptable results can not be obtained in 6/1, naturally meaningful results could not be obtained with 6/2 and 6/3. This is true for all three methods. Therefore, 6/2 and 6/3 are excluded by having 30 configurations instead of 36. However, it is understandable that any occlusion affects the results in the 6-point object case. Since there are very few points, every point is critical in finding the true pose.

GPE is especially very good in finding the position. Note that position error is evaluated in relative terms to the size of the object. That is why  $\varepsilon_p$ , as shown in equation (5.13), is

calculated by normalizing the position error by the object diameter (i.e., twice the object radius).

Looking at the error figures in Table 5.2, Table 5.3 and Table 5.4, the best performing algorithm is apparently GPEsoftPOSIT. Figure 5.5 and 5.6 try to summarize the tendencies of the orientation and position error, respectively. Before looking at the bar graphs in Figure 5.5 and 5.6 more closely, let state the expected tendencies:

- i) Error should go up as the number of occluded points goes up.
- ii) Error should go down as the number of object points goes up.
- iii) Error should go up as the relative distance goes up.

If the gross errors are excluded introduced by 6/1, it can be more or less seen that error goes up as the number of occluded points goes up (Figure 5.5a and 5.6a). In Figure 5.6c and 5.6d, as expected it is seen that (relative) position error goes down as the number of object points goes up. In Figure 5.5c and 5.5d, this tendency is not obvious for orientation error. This may be due to the fact that the images used are synthetic. In real-life (i.e., real images), more object points compensate for the inaccuracies introduced by pixelization, imaging system, and feature detection. Similarly in Figure 5.5e, 5.5f, 5.5e, and 5.5f, it is seen the expected tendency in position error graphs but not orientation error graphs. Errors had been plotted both for no occlusion and also for all tests. If no occlusion tests have an error of  $x$  (Figure 5.5c, 5.5e, 5.6c, 5.6e), the average of all tests seem to be around  $2x$  (Figure 5.5d, 5.5f, 5.6d, 5.6f).

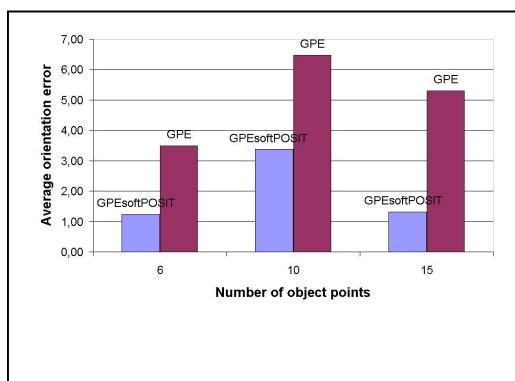

CPU times are listed in Table 5.2, Table 5.3 and Table 5.4. GPE and GPEsoftPOSIT almost have equal times as GPEsoftPOSIT runs SoftPOSIT only once. GPE and GPEsoftPOSIT take between half to one minute, while 500 runs of SoftPOSIT in random start SoftPOSIT take between 50 to 95 seconds. The computational complexity of GPE is governed by the number of iterations and number of feature points. In most tests, GPE went up to the preset maximum of 50,000 iterations. The most compute-intensive operation inside a GPE iteration is the computation of correspondence (see the pairing algorithm in Section 4.1). The complexity of this algorithm is, on the other hand, dominated by the sorting of LOS and object point distances, which is in the order of  $n^2 \log n$ , where  $n$  is the number of object points.

## 6. VISUALIZATION

GPE tries various poses to find the accurate pose of an object. To display the trajectory of the object a visualization program has been written. The program has been developed by using Open-GL. The code written has not been performed a simultaneous simulation by integrating into GPE. It is because of that these types of processes use too much memory and make the processor work intensively. In addition, as it may cause some incompatibilities related to code; it is thought that using of different GPE and simulation codes as the two programs would be more productive. Besides, as thousands of iterations have been tried to get the best pose; not each but the better pose than before has been used. By the way, it is simulated how the good results have been achieved by using this pose information. In order to provide integration between the two programs, GPE writes better pose into a text file top and bottom, and the simulation program received this file as an input and formed an output in accordance with the information from the file. While creating output, the object shall be placed into the better pose that GPE has found. At last, the coordinate where the object is placed is the best pose which GPE has found for the object. In Figure 6.1, simulation belonging to one of the experiments can be followed step by step.

## 7. CONCLUSION

An  $n$ -point feature-based correspondenceless pose estimation method (called GPE for Gravitational Pose Estimation) for rigid objects, which uses a single perspective image with no restrictions on the object's pose, is hereby presented. GPE is stand on an intuition from classical mechanics.

Good results are presented using both synthetic and real-world images. In the thesis real-world images have been taken with a cheap webcam with an obvious fish-eye effect (Figure 5.1) and still quality results are obtained. GPE had been successfully tested against occlusion as well – with a test suite of 300 synthetic images.

The inputs and the outputs for carrying out of the pose estimation algorithms where the programs are places have been automated as a whole and provide an improved ease of use. In addition to this, processes have been visualized step by step in order to be better understood how the program positions the object, observably.

In this thesis, GPE with SoftPOSIT for fine-tuning of the pose is integrated. After the integration, globally optimum pose correspondence and determination in 62% of the test cases (185 out of the 300) have been achieved. Averagely (including up to 30% occlusion cases but excluding the 6/1 case), GPE finds the orientation within 6 degrees and the position within 17% of the object's diameter. GPEsoftPOSIT, on the other hand, is within 3 degrees and 10% of the object's diameter in the same set of tests.
